Short Title: How I Treat Waldenstrom Macroglobulinemia.

Keywords: Waldenström macroglobulinemia, MYD88, CXCR4, rituximab, bortezomib, bendamustine, ibrutinib.
Abstract

Waldenström’s macroglobulinemia (WM) is a B-cell neoplasm manifested by the accumulation of clonal IgM secreting lymphoplasmacytic cells. MYD88 and CXCR4 WHIM-like somatic mutations are present in >90%, and 30-35% of WM patients, respectively, and impact disease presentation, treatment outcome, and/or overall survival. Familial predisposition is common in WM. Asymptomatic patients should be observed. Patients with disease related hemoglobin <10g/L, platelets <100x10^9/L, bulky adenopathy and/or organomegaly, symptomatic hyperviscosity, peripheral neuropathy, amyloidosis, cryoglobulinemia, cold-agglutinin disease or transformed disease should be considered for therapy. Plasmapheresis should be used for patients with symptomatic hyperviscosity, and pre-rituximab for those with high serum IgM levels to pre-empt a symptomatic IgM flare. Treatment choice should take into account specific goals of therapy, necessity for rapid disease control, risk of treatment-related neuropathy, immunosuppression and secondary malignancies, and planning for future autologous stem cell transplantation. Frontline treatments include rituximab alone, or combined with alkylators (bendamustine, cyclophosphamide), proteasome-inhibitors (bortezomib, carfilzomib), nucleoside-analogues (fludarabine, cladribine) and ibrutinib. In the salvage setting, an alternative frontline regimen, ibrutinib, everolimus, or stem cell transplantation can be considered.
Investigational therapies under development for WM include agents that target MYD88, CXCR4, BCL2, and CD27/CD70 signaling, novel proteasome inhibitors, and chimeric antigen receptor modified T-cell therapy.
**Introduction**

The cases presented in Table 1 revealed Waldenström’s macroglobulinemia (WM), a B-cell neoplasm resulting from the accumulation of clonal lymphoplasmytic cells (LPC) secreting a monoclonal IgM protein. WM patients can present with a wide array of symptoms and findings that impact diagnostic work-up and treatment. MYD88 and CXCR4 WHIM-like somatic mutations are present in >90%, and 30-35% of WM patients, respectively, but are absent or rare in other IgM secreting B-cell malignancies. Over half of individuals with IgM secreting monoclonal gammopathy of unknown significance (MGUS) harbor the MYD88<sup>L265P</sup> mutation, suggesting its role as an early oncogenic driver. Somatic CXCR4 mutations are similar to those found in the germline of WHIM (Warts, Hypogammaglobulinemia, Infections, Myelokathexis) syndrome, and nearly always are present in WM patients with MYD88<sup>L265P</sup>. Both nonsense (CXCR4<sup>WHIM/NS</sup>) and frameshift CXCR4 mutations (CXCR4<sup>WHIM/FS</sup>) occur in WM patients. MYD88 and CXCR4 mutations may impact disease presentation, treatment outcome, and/or survival.<sup>3-14</sup> Low tumor burden and serum IgM levels are associated with wild-type MYD88 (MYD88<sup>WT</sup>) disease, while MYD88<sup>L265P</sup> patients with CXCR4<sup>WHIM</sup> mutations have higher BM disease burden. High serum IgM levels including presentation with hyperviscosity crisis have been observed in
patients with CXCR4$_{WHIM/FS}^{WHIM/PS}$ tumor mutation status. Ibrutinib response (discussed below) is adversely impacted by MYD88$^{WT}$ and CXCR4$_{WHIM}^{WHIM}$ status. In one study, overall survival was lower in patients with MYD88$^{WT}$ disease, but was unaffected by CXCR4 mutation status.

**Clinical Features**

The clinical and laboratory findings for a large series of newly diagnosed patients who presented to the WM clinic at the Dana Farber Cancer Institute (a tertiary referral center) are depicted in Table 2. Splenomegaly and lymphadenopathy (as with Case 2) are uncommon at initial presentation (15-20%), though at later stages extra-medullary disease is more common (up to 60% of patients). WM-related morbidity may be manifested by tumor cell infiltration, and/or by the physicochemical and immunological properties of the monoclonal IgM protein produced by WM cells (Table 3).

**Diagnostic Workup**

**History taking**
Familial predisposition is strong in WM.\textsuperscript{22-24} Familial WM patients are younger, have a higher disease burden, and show lower response rates and progression-free survival (PFS) with non-proteasome inhibitor based therapy.\textsuperscript{25} Hepatitis C exposure as a WM predisposition remains controversial though is associated with Type II cryoglobulinemia.\textsuperscript{26-28} A thorough review of systems should be performed given a wide-range of WM-related morbidity that exists which can impact the diagnostic work-up and treatment undertaken (Table 4).

**Laboratory Studies**

To establish the WM diagnosis, an IgM monoclonal protein and BM LPL infiltration must be present.\textsuperscript{1} No minimum serum IgM or BM infiltration level is required to diagnose WM, since patients can be symptomatic and need treatment at low serum IgM (<1,000 mg/dL) levels or BM disease involvement.\textsuperscript{29} Laboratory and clinical evaluations which can be performed in the initial work-up of all WM patients, and those with particular disease-related features are presented in Table 4.
Treatment Approaches to WM

Management of the Asymptomatic WM Patient

Patients with disease-related hemoglobin level (<10 g/dL), platelet count <100x10^9/L, or symptomatic disease manifested by hyperviscosity, amyloidosis (particularly if there is heart involvement), cryoglobulinemia, cold-agglutinemia, extramedullary disease including central nervous system (Bing-Neel syndrome) involvement, moderate-severe, or advancing paraprotein-related peripheral neuropathy (PN), or disease transformation should be considered for therapy. Treatment initiation should not be based on serum IgM levels per se, though at higher serum IgM levels (>6,000 mg/dL) empiric treatment may be appropriate to prevent hyperviscosity-related injury.

Management of the Symptomatic WM patient

Treatment choice should take into account specific goals of therapy,
necessity for rapid disease control, risk of treatment-related neuropathy, immunosuppression, secondary malignancies, and potential for future autologous stem cell transplantation (ASCT). Hepcidin-related iron deficiency is common in WM patients. In select patients with low disease burden, symptomatic anemia, and depressed iron saturation levels (i.e. <10-12%) unrelated to gastrointestinal bleeding, parenteral iron administration may be beneficial. If unresponsive to parenteral iron, chemotherapy can then be initiated. Plasmapheresis should be considered for patients in need of immediate paraprotein control (discussed below), and pre-rituximab if serum IgM is >4,000 mg/dL to pre-empt a symptomatic IgM flare. A suggested algorithm for the primary therapy of WM is provided in Figure 1. Continuous oral alkylator therapy (such as chlorambucil) and nucleoside-analogues should be avoided in ASCT candidates to prevent stem cell damage, as well as in younger patients (<65-70 years) given their association with secondary malignancies and/or disease transformation.

Frontline Therapy of Waldenstrom’s Macroglobulinemia

For symptomatic, untreated WM patients not requiring immediate disease control as exemplified in Case 1, options include rituximab alone, or with
alkylators (bendamustine, cyclophosphamide), proteasome-inhibitors (bortezomib, carfilzomib), nucleoside-analogues (fludarabine, cladribine), and ibrutinib. Rituximab alone is well-suited for more indolent WM patients, i.e. those with mild-moderate symptomatic anemia or PN (as for Case 1), and those for whom more aggressive chemotherapy is inappropriate. Rituximab monotherapy should not be used in a patient in whom rapid responses are required, since response times can be slow. In addition, a rituximab-induced IgM flare (defined as \( \geq 25\% \) increase above baseline serum IgM level) occurs in 40-60% of WM patients and can provoke or accentuate IgM related morbidity including symptomatic hyperviscosity, PN, cold agglutinemia and cryoglobulinemia.\(^{38-42}\) Rituximab monotherapy produces overall response rates (ORR) of 25-40\% with standard (375 mg/m\(^2\)/week for 4 weeks) therapy, and 40-60\% with extended (375 mg/m\(^2\)/week at weeks 1-4, 12-16) therapy with median PFS estimates of 16-29+ months.\(^{43-45}\) Rituximab-related infusion reactions are common in WM patients, and administration of oral dexamethasone (10 mg) and famotidine (20 mg) the night before rituximab administration in addition to standard hypersensitivity prophylaxis may help reduce these events. Despite prophylaxis, progressive rituximab-intolerance is commonly encountered in WM, and ofatumumab may successfully be administered in place of rituximab.\(^{46,47}\)
For untreated WM patients experiencing non-emergent paraprotein related morbidity, a proteasome-inhibitor containing regimen such as bortezomib, dexamethasone and rituximab (BDR) or carfilzomib, rituximab and dexamethasone (CaRD) is ideal.\textsuperscript{48-50} Proteasome-inhibitor containing therapy can also be considered for myelosuppressed patients, though rarely bortezomib causes thrombocytopenia. In younger patients for whom avoidance of alkylator-based therapy is desired to reduce risk of secondary malignancies, proteasome-inhibitor based therapy (or ibrutinib discussed below) can be considered. Bortezomib is best avoided in patients with paraprotein-related neuropathy as in Case 1 given risk for treatment-related neuropathy. For BDR, weekly administration of bortezomib reduces but does not abrogate treatment-related neuropathy.\textsuperscript{49} There is no data on subcutaneous bortezomib use in WM patients, but can be considered given the lower neuropathy risk observed with this method of administration in myeloma patients.\textsuperscript{51} Regardless of route for administration, a close watch for bortezomib-related neuropathy should be undertaken, and drug held for grade $\geq 2$ neuropathy. For weekly BDR, bortezomib can be dosed at 1.6 mg/m$^2$/week with dexamethasone (20 mg/week) for 12-16 weeks, based on patient tolerance. Rituximab can be introduced if the baseline serum IgM is $<4,000$ mg/dL, or when such a level is achieved on weekly bortezomib and
dexamethasone alone. Plasmapheresis to lower the serum IgM to <4,000 mg/dL pre-rituximab can also be considered.\textsuperscript{30,33} One single dose of rituximab (375 mg/m\textsuperscript{2}/week) can be given every 3-4 weeks as part of the weekly BDR regimen. Serum IgM levels should be carefully monitored to detect a rituximab-related IgM flare. Maintenance can be considered for BDR responders (discussed below).

The CaRD regimen which is associated with a low incidence of treatment-related neuropathy can also be considered in non-emergent patients.\textsuperscript{50} Serum IgA and IgG depletion is pronounced with CaRD which incorporates an extended maintenance schedule, and can contribute to recurring sinus and bronchial infections. A modified CaRD regimen with one rituximab infusion per induction cycle, or an abbreviated maintenance course may be considered to reduce serum IgA and IgG depletion.\textsuperscript{50} Rituximab should only be introduced when the serum IgM is <4,000 mg/dL. Transient increases in amylase, lipase and bilirubin commonly occur with CaRD, and should be monitored. Carfilzomib should be avoided in patients at risk of cardiomyopathy. With either BDR or CaRD, herpes zoster prophylaxis with oral antiviral therapy (i.e. acyclovir 400 mg twice daily) for the duration of active therapy plus six months should be given, as well as famotidine (20
mg BID) during active therapy to decrease risk of gastrointestinal irritation.

For patients with bulky extramedullary disease, malignant pleural effusions or heavily impacted BM involvement, alkylator-based (bendamustine or cyclophosphamide) therapy can be considered. Benda-R showed longer (69 versus 29 months) PFS, and better tolerance versus CHOP-R in WM patients included in a randomized study by the German STiL group.\textsuperscript{52} Bendamustine can be administered intravenously at 90 mg/m\textsuperscript{2} on days 1, 2 every 4 weeks for 4-6 cycles, though 4 cycles is sufficient for most WM patients, and may reduce risk of prolonged or late myelosuppression. Bendamustine dose should be reduced in elderly patients (i.e. to 60-70 mg/m\textsuperscript{2} on days 1, 2 every 4 weeks), and those with diminished renal function. Rituximab should be introduced when the serum IgM level is <4,000 mg/dL with Benda-R. A cyclophosphamide-based regimen such as rituximab, oral cyclophosphamide and dexamethasone (R-CD) can be considered as an alternative to Benda-R.\textsuperscript{30,33} The ORR with R-CD or similar regimens are 80-90% with a median PFS of 3 years.\textsuperscript{53-55} R-CHOP or R-CVP is not advantageous over R-CD or R-CP, and can contribute to more toxicities including treatment-related neuropathy.\textsuperscript{55} Maintenance therapy following Benda-R or R-CD can be considered in responders (discussed below).
Nucleoside-analogues with rituximab and/or cyclophosphamide in untreated WM patients are associated with ORR of 85-95%, with a median PFS of 4 years.\textsuperscript{56-59} It is unclear whether including cyclophosphamide to a nucleoside-analogue containing regimen (such as FCR) extends activity in WM, and may contribute to added toxicity. Because of immunosuppression, myelosuppression, impact on stem cell collection, and potential secondary malignancy risks including disease transformation, nucleoside-analogues should be cautiously used.\textsuperscript{34-37,56-59} An exception may be for WM patients with Bing-Neel syndrome, for whom CNS responses can be obtained with fludarabine.\textsuperscript{60} WM patients >70 years, and non-ASCT candidates may also be candidates for nucleoside-analogue therapy.\textsuperscript{31,34} In elderly patients, fewer days of therapy per cycle, and fewer treatment cycles may be considered to minimize fludarabine-related toxicity.\textsuperscript{57} Herpes zoster prophylaxis should be given for the duration of nucleoside-analogue treatment, and for at least one-year from end of active nucleoside-analogue therapy.\textsuperscript{57} Cytokine support per ASCO guidelines should be considered with alkylator or nucleoside-analogue based therapies.\textsuperscript{61}

Ibrutinib was recently approved by the U.S. Food and Drug Administration, and adopted into National Comprehensive Cancer Network
(NCCN) guidelines for symptomatic WM patients. While data on the activity of ibrutinib in WM is based on previously treated patients (discussed below), the number of prior lines of therapy had no impact on its activity. Moreover, less pre-treated WM patients showed better PFS, and less toxicity. However, patients with MYD88WT had considerably lower response rates and shorter PFS, while those with CXCR4 mutations showed slower initial response that improved with prolonged (>6 months) therapy. The rapid time to IgM reduction (4 weeks), and absence of a rituximab-like IgM flare effect make the use of ibrutinib particularly attractive for patients with high IgM levels (in whom use of rituximab would be problematic), as well as those with IgM-related morbidity. There is no data on ibrutinib use in patients with Bing-Neel Syndrome, or bulky adenopathy (>5 cm), though reductions in extramedullary disease occurred in most previously treated patients on ibrutinib. The use of ibrutinib (if available) can be considered in symptomatic frontline patients, though alternative options should be considered for patients with bulky disease, and MYD88WT disease. Ibrutinib should be avoided in patients on warfarin, low platelet counts, and bleeding. Patients with a prior history of arrhythmia may also experience tachyarrhythmias while on ibrutinib, and either close monitoring or alternative treatment options should be sought. To minimize bleeding risk associated with ibrutinib, any fish oil supplements should be discontinued, and drug
withheld for 3 to 7 days before and for 1 to 3 days after an anticipated invasive procedure.\textsuperscript{14}

**Treatment of the WM Patient Requiring Immediate Disease Control**

For WM patients requiring immediate paraprotein control (as in Case 2), plasmapheresis should initially be performed.\textsuperscript{30,33} Typically 2-3 sessions of plasmapheresis reduce serum IgM levels by 30-60\%.\textsuperscript{62,63} Red blood cell transfusions (if required) should ideally follow plasmapheresis to not aggravate the viscosity load.\textsuperscript{63} Blood-warmers should be used during plasmapheresis in patients with cryoglobulinemia or cold-agglutinemia to prevent cryoprecipitation and/or erythrocyte agglutination.

Treatment should be initiated as soon as possible after plasmapheresis, as serum IgM levels will return to baseline in 4-5 weeks.\textsuperscript{63} Ibrutinib (if available) may be ideal in such a setting, given the rapid time to IgM reduction (median 4 and 8 weeks to at least a minor and major response, respectively). If ibrutinib is not available, modified BDR consisting of bortezomib at 1.3 mg/m2 and dexamethasone 20 mg can be given twice weekly (on days 1, 4, 8, 11 every 21 days) for the first 1-2 cycles.\textsuperscript{49} Once
the patient is stabilized, bortezomib (1.6 mg/m2) and dexamethasone (20 mg) can be given weekly, and up to 16 weeks (in total) of therapy can be considered. Rituximab (375 mg/m2/week) every 3-4 weeks can be integrated into BDR once the serum IgM is under 4,000 mg/dL. In some patients the serum IgM may remain unsafely high and continuance of twice-weekly bortezomib may be required. A close watch for bortezomib-related neuropathy should be maintained, and treatment held for grade ≥2 neuropathy. CaRD can also be considered which is associated with low treatment-related neuropathy risk.50 As an alternative, bendamustine based therapy (as discussed above) can be considered.52 The serum IgM should be carefully monitored for a few weeks after rituximab is initiated to monitor for an IgM flare. Maintenance therapy can be considered for responders and is discussed below.

**Treatment of Paraprotein Related Peripheral Neuropathy**

For patients with mild, progressive IgM-related PN (such as Case 1), rituximab alone can be considered though its clinical impact remains in question.64–67 Frequently, patients show a hematological response, without improvement in PN symptoms. The depth of response, and elapsed time
between manifestation of PN symptoms and therapy can be factors.\textsuperscript{68} In patients with chronic, longstanding PN, the goal is to prevent symptomatic progression as myelin regeneration occurs very slowly. For patients with moderate to severe IgM-related PN, combination therapy with rituximab may also be effective.\textsuperscript{67,68} Ibrutinib has shown symptomatic improvement in WM patients with IgM-related PN that progressed after rituximab, and is also reasonable.\textsuperscript{69} In patients presenting with rapidly evolving IgM-related PN, interim plasmapheresis may be useful before instituting definitive chemotherapy. Steroid or IVIG use is of little value in the treatment of IgM-related PN.\textsuperscript{68} Proteasome-inhibitor based therapy can be considered for amyloid or cryoglobulin related PN, using either weekly dosed bortezomib or carfilzomib to minimize risk of treatment-related neuropathy. As before, proteasome inhibitor therapy should be held for grade $\geq 2$ treatment-related neuropathy. Cryoglobulin-related PN should only be treated if chronic symptoms are present, and not for transient, cold-induced episodic events.

**Therapy in previously treated WM**

A suggested algorithm for the therapy of previously treated WM patients is provided in Figure 2. The overall response rate for ibrutinib in previously
treated WM patients was 91%, with 73% of these patients achieving a major response.\textsuperscript{14} The 2-year estimate for progression-free and overall survival in this study was 69% and 95% respectively. Overall and major response rates were highest among patients with the MYD88\textsuperscript{L265P}CXCR4\textsuperscript{WT} genotype (100.0% and 91.2%), followed by MYD88\textsuperscript{L265P}CXCR4\textsuperscript{WHIM} (85.7% and 61.9%) and MYD88\textsuperscript{WT}CXCR4\textsuperscript{WT} (71.4% and 28.6%), respectively. Both major responders among the 7 patients with MYD88\textsuperscript{WT}CXCR4\textsuperscript{WT} were subsequently found to harbor other MYD88 mutations.\textsuperscript{70}

Overall, ibrutinib was well tolerated, though neutropenia and thrombocytopenia were more common in heavily pre-treated patients. Serum IgA and IgG levels remained unchanged following ibrutinib, and treatment-related infections were infrequent. Patients should be maintained on ibrutinib until evidence of progression, or intolerance despite dose-reduction. Transient increases in serum IgM frequently occurred when ibrutinib was withheld, and did not signify treatment failure as IgM levels declined upon reinstatement of therapy.\textsuperscript{14}

While ibrutinib represents an ideal treatment strategy for relapsed or refractory WM (as in Case 3), it is not available in many countries. The use
of an alternative first-line agent (as discussed above) can be considered if ibrutinib is not available. In patients for whom ASCT is seriously being considered, exposure to stem-cell damaging agents such as chlorambucil or nucleoside-analogues should be avoided, and a non-stem-cell toxic approach considered if stem cells have not been previously harvested.\textsuperscript{30,33}

Everolimus has been investigated in WM. In previously treated WM patients, the overall and major response rates to everolimus were 73% and 50% respectively, with a median PFS of 21 months.\textsuperscript{69} Grade \( \geq 3 \) toxicities, particularly cytopenias, are common with everolimus. Pulmonary toxicity can also occur, and managed with steroids. Among untreated, symptomatic WM patients, the overall and major response rates for everolimus were 72% and 60%, respectively.\textsuperscript{71} Discordance between serum IgM levels and BM disease response were commonly encountered in the frontline study which mandated serial bone marrow assessments. Oral ulcerations frequently occurred with everolimus, which could be prevented with an oral dexamethasone swish and spit solution. Because of its toxicity profile, and frequent toxicity-related treatment discontinuation, everolimus should be considered for third or beyond line of therapy in WM patients.
Stem cell transplantation (SCT) remains an option for salvage therapy in WM, particularly among younger patients who have had multiple relapses, or those patients with primary refractory disease. In an EBMTR study, the 5 year progression-free and overall survival were 40% and 69%, respectively, for patients with predominately multi-relapsed or refractory disease who received ASCT. The non-relapse mortality at one-year was low (4%), and the presence of chemo-refractory disease and number of prior therapies impacted both progression-free and overall survival in this study. WM patients with amyloidosis may also benefit from ASCT. The outcome of previously treated WM patients who received myeloablative and reduced-intensity allogeneic transplantation was also reported by the EBMTR. Most patients (69%) in this series had chemotherapy-sensitive disease. The ORR was 76%, and the 5-year progression-free and overall survival rates were 56% and 62%, respectively. Among patients who received reduced-intensity allogeneic transplantation, similar progression-free and overall survival rates were observed (49% and 64%). Non-relapse mortality at 3 years was high, at 33% and 23% for myeloablative and reduced-intensity allogeneic transplantation, respectively. ASCT, and in very select cases, reduced-intensity allogeneic transplantation may be considered as appropriate salvage modalities, though the risks and benefits of these modalities should be carefully weighed against other available treatment options including
ibrutinib (if available).\textsuperscript{30,33}

**Maintenance Therapy in WM**

Maintenance rituximab therapy may be considered in WM patients responding to a rituximab-containing induction regimen.\textsuperscript{30,33} In a large retrospective study, post-induction categorical responses improved in 42\% of patients receiving maintenance rituximab versus 10\% in those on watch-and-wait.\textsuperscript{75} Progression-free and overall survival was longer for patients on maintenance rituximab as well. However, more infectious events (usually grade 1 or 2 sinusitis or bronchitis) and lower serum IgA and IgG levels were observed in patients on maintenance therapy. A prospective randomized study examining maintenance rituximab versus observation has been initiated by the German STiL group, and results awaited.\textsuperscript{76}

The optimal dosing schedule for maintenance rituximab therapy in WM patients remains unclear. A single rituximab infusion (375 mg/m\textsuperscript{2}) every 3 months for 2 years (as per Van Oers et al\textsuperscript{77}) is reasonable over more frequent dosing to minimize rituximab-related serum IgA and IgG depletion.\textsuperscript{78} Maintenance therapy should be discontinued in WM
patients with low serum IgG and/or IgA levels and recurring sinobronchial infections (>3-4/year) that require antibiotic support, or who experienced a severe infection requiring hospitalization.

Combined maintenance therapy with rituximab and dexamethasone and either bortezomib or carfilzomib has been investigated in WM, and can be considered for WM patients who received BDR or CaRD induction, respectively. Serum IgA and IgG depletion may be more pronounced with proteasome-inhibitor containing maintenance regimens, and their levels should be closely monitored. Shorter courses or longer intervals between cycles may help minimize serum IgA and IgG depletion, and can be considered in maintenance strategies that use BDR or CaRD. Neuropathy may also be potentiated with bortezomib containing maintenance regimens and should be carefully monitored, and treatment held for grade >2 treatment-related PN.

Response Assessment

Consensus response criteria have been developed as part of the International Workshops on WM. A “major response” denotes a > 50%
decrease in serum IgM levels, and includes partial and complete responses, while the ORR includes minor responders. Durable clinical benefit has been shown in minor responders, while deeper categorical responses such as VGPR or CR are associated with longer PFS.\textsuperscript{80,81} Response categories and criteria for progressive disease in WM are summarized in Table 5. Either the serum IgM or the IgM monoclonal spike may be used to track disease burden in WM patients.\textsuperscript{82} However, gel migration patterns for the IgM paraprotein can vary and confound serial IgM monoclonal spike assessments in many cases.\textsuperscript{83} In patients with cryoglobulinemia, serum samples should be obtained on warm baths (or equivalent) to minimize cryoprecipitation and serum IgM underestimation. Serum IgM levels can fluctuate with certain biological agents including rituximab, everolimus, bortezomib, and ibrutinib.\textsuperscript{14,38,39,70,84} In circumstances when the serum IgM levels appear out of context with clinical impression, a BM biopsy should be considered.

**Novel Agents for WM**

Investigational therapies under development for WM include agents that target MYD88, CXCR4, BCL2, and CD27/CD70 signaling, novel proteasome inhibitors, and chimeric antigen receptor (CAR) modified T-cell therapy. Idelalisib blocks PI3Kδ, a growth promoting transcription factor that
is activated by MYD88$^{L265P}$.$^{85,86}$ A 70% ORR was observed among ten previously treated WM patients evaluated in a larger study, and a prospective study in previously treated WM patients is forthcoming. IMO-8400 is an oligonucleotide that inhibits Toll-receptors 7, 8, and 9, and induces apoptosis in MYD88$^{L265P}$ WM cells.$^{87}$ A clinical trial examining IMO-8400 in WM has been initiated. IRAK1/IRAK4 kinases mediate MYD88$^{L265P}$ directed NFkB signaling, and their inhibition triggers apoptosis in MYD88$^{L265P}$ expressing malignant cells.$^{7,88}$ Moreover, combined BTK and IRAK1/4 inhibition induces synergistic killing of MYD88$^{L265P}$ malignant cells.$^{88}$ Compounds that inhibit IRAK signaling are under intense preclinical investigation for use in MYD88$^{L265P}$ diseases.$^{89,90}$ The anti-apoptotic factor BCL-2 is over-expressed in WM cells.$^{91,92}$ The BCL-2 inhibitor ABT-199 induces apoptosis, and shows at least additive anti-apoptotic activity against WM cells co-treated with either ibrutinib or idelalisib.$^{93}$ In a prospective clinical study, 3 of 4 WM previously treated WM patients responded, that included one CR.$^{94}$

Oprozomib is an oral epoxyketone proteasome-inhibitor that is an analog of carfilzomib.$^{95}$ An ORR of 59% was observed in a phase 2 study in previously treated WM patients.$^{96}$ Clinical trials examining the oral proteasome-inhibitor ixazomib have also been initiated in combination with dexamethasone
and rituximab in symptomatic untreated, as previously treated WM patients. 

97,98 Soluble CD27 (sCD27) is released by WM cells, and stimulates growth promoting ligands through CD70.99 CD70 is also expressed on WM cells.100 A clinical trial examining a novel human anti-CD70 (ArgenX-70) antibody that mediates ADCC and blocks sCD27-CD70 signaling is being initiated in previously treated WM patients.101 In pre-clinical studies, CXCR4 antagonists blocked SDF-1a rescue of apoptosis mediated by ibrutinib, idelalisib, and other therapeutics.10,102,103 A trial examining ibrutinib with the anti-CXCR4 antibody ulocuplumab (BMS-936564) is being planned in WM patients given encouraging safety and efficacy data in myeloma patients, as well as in vivo results with ulocuplumab in mice engrafted with CXCR4WHIM mutated WM cells.10,104 Chimeric antigen receptor (CAR) modified T-cell therapy utilizing a second generation CAR derived from a CD19-directed antibody fused to the ζ chain of CD3, and the intracellular signaling domain of CD28 (19-28z) has shown robust preclinical activity against WM cells.105 A clinical trial for relapsed or refractory WM patients using 19-28z CAR modified autologous T-cells has been initiated.
Case Management

Case 1. Given the non-urgent nature of this WM patient’s presentation, rituximab was started for progressive, symptomatic IgM-related neuropathy. The patient did encounter an IgM flare, and worsening neuropathic symptoms. He underwent plasmapheresis and was transitioned to CDR, and achieved a PR with near resolution of his neuropathic symptoms. He completed 2-years of maintenance rituximab therapy, and remains in a partial response, without peripheral neuropathy, five-years later. Under similar circumstances today, ibrutinib (if available) could be considered as an appropriate initial or second line intervention.

Case 2. This 42-year old WM patient presented with symptomatic hyperviscosity. The patient also had bulky adenopathy and splenomegaly at the time of presentation. He underwent emergent plasmapheresis, and then received blood transfusions so as to not aggravate whole blood viscosity levels. Given his young age, and need for rapid paraprotein reduction, bortezomib and dexamethasone (without rituximab to avoid an IgM-flare) was started. Serum IgM levels were closely monitored post-pheresis, and he received additional plasma exchanges when serum IgM exceeded 5,000.
After three cycles of bortezomib and dexamethasone no response occurred, and he was started on bendamustine. The serum IgM level decreased to 3,400 mg/dL following 2 cycles of bendamustine, and no further plasmapheresis was required. Rituximab was then added to bendamustine for 4 additional cycles, with continued close monitoring of serum IgM levels. Maintenance rituximab therapy followed for 2 additional years, and he achieved a VGPR with complete resolution of all extramedullary disease. Two-years after treatment, he remains without progression, though has required IVIG replacement for recurring sino-bronchial infections associated with treatment related serum IgA and IgG depletion. Under similar circumstances today, ibrutinib (if available), would represent a very reasonable option to use either as initial or subsequent therapy. The IgG and IgA sparing effects associated with ibrutinib may have also prevented the need for IVIG replacement in this patient.

**Case 3.** This case illustrates a young WM patient refractory to multiple agents. Nucleoside analogues, alemtuzumab and allogeneic stem cell transplantation were considered, though the patient declined these options because of toxicity concerns. A BM biopsy confirmed persistent WM disease with a MYD88<sup>L265P</sup>CXCR4<sup>WT</sup> genotype. He received ibrutinib on a clinical trial and attained a partial response. Post-therapy, his hematocrit normalized.
and he remains in a partial response 2.5 years later.

Figure 1. Guide to the Primary Therapy of Waldenstrom’s Macroglobulinemia. HV, hyperviscosity; CRYO, Cryoglobulinemia; CAGG, Cold Agglutinemia. BDR (Bortezomib, Dexamethasone, Rituximab); Benda-R (Bendamustine, Rituximab); CaRD (Carfilzomib, Rituximab, Dexamethasone); CDR (Cyclophosphamide, Dexamethasone, Rituximab); FR (Fludarabine, Rituximab), IB (Ibrutinib), R (Rituximab). ¹Consider blood warmers with plasmapheresis in patients with cryoglobulinemia or cold agglutininemia to avoid cryoprecipitation or agglutination. ²Can be considered in patients who are not wild-type for MYD88, and for those patients without bulky adenopathy or Bing-Neel Syndrome. ³For patients requiring immediate disease control, consider twice weekly dosed bortezomib for 1-2 cycles, then if patient stable switch to weekly bortezomib to reduce risk of treatment related peripheral neuropathy. In patients not requiring immediate disease control, the use of weekly dosed bortezomib is preferable. Bortezomib should be avoided in patients with disease related neuropathy. Bortezomib should be held for grade >2 treatment-related neuropathy. Acyclovir and famotidine (or equivalent) are strongly recommended for patients on proteasome inhibitor therapy. ⁴Rituximab should be held in patients with symptomatic HV, severe CRYO or CAGG, and in asymptomatic patients with serum IgM >4,000 mg/dL to avoid an IgM flare and potentiation of symptoms. Ofatumumab may be considered for rituximab intolerant patients. Consider maintenance rituximab for patients responding to a rituximab-containing regimen. See text for suggested dosing, cycles and scheduling of therapy. A clinical trial should be considered whenever possible.
Figure 2. Guide to therapy of previously treated Waldenstrom’s Macroglobulinemia. ASCT (Autologous Stem Cell Transplant); RIC (Reduced Intensity Allogeneic Stem Cell Transplant); IB, Ibrutinib; NA; nucleoside-analogue based therapy. ¹Can be considered in patients not previously treated with IB, and who are not wild-type for MYD88, and for those patients without bulky adenopathy or Bing-Neel Syndrome. ²In patients being considered for an ASCT, stem cell collection should be undertaken before exposure to a nucleoside-analogue. Rituximab should be held in patients with symptomatic HV, severe CRYO or CAGG, and in asymptomatic patients with serum IgM >4,000 mg/dL to avoid an IgM flare and potentiation of symptoms. Ofatumumab may be considered for rituximab intolerant patients. Consider maintenance rituximab for patients responding to a rituximab-containing regimen. Bortezomib should be held for grade ≥2 treatment-related neuropathy. See text for suggested dosing, cycles and scheduling of therapy. A clinical trial should be considered whenever possible.

Symptomatic Relapse or Refractory Disease

ASCT Eligible

Avoid oral alkylators
Avoid nucleoside analogues

Refractory or 1st relapse < 2 years since last therapy.

1st choice: IB
Alternate: Consider alternative first line regimen to that used.

Multiple relapses: Everolimus, NA, ASCT or RIC Allogeneic SCT (in select cases)

ASCT Ineligible

Refractory or 1st relapse < 2 years since last therapy.

1st choice: IB
Alternate: Consider alternative first line regimen to that used.

Multiple relapses: Everolimus.

1st relapse > 2 years since last therapy.

1st choice: IB
Alternate: Consider re-use of previous first line therapy.

1st relapse > 2 years since last therapy.

1st choice: IB
Alternate: Consider re-use of previous therapy.

Consider alternative first line regimen to that used.
Case 1. WM Patient with IgM-related Peripheral Neuropathy.

A 67 year-old patient complained of numbness and tingling in his toes that extended above the ankles over several months. Exam revealed diminished pinprick sensation over the soles of his feet. An IgMλ monoclonal protein was discovered, with a serum IgM level of 640 mg/dL. A bone marrow (BM) biopsy showed 10% involvement with lymphoplasmacytic lymphoma (LPL), and the MYD88<sup>L265P</sup> mutation was present. Fat-pad biopsy with congo-red staining was negative. An anti-MAG IgM antibody screen was markedly positive with a titer >1:102,400.
Case 2. Newly diagnosed WM patient in Hyperviscosity Crisis.

A 42 year-old male presented with blurry vision and nosebleeds. Exam revealed retinal hemorrhages, adenopathy and splenomegaly. Laboratories revealed a hematocrit of 18%, platelets of 50,000/mm³, and leukocyte count of 1500/mm³. Serum total protein was high prompting a workup that revealed an IgMλ monoclonal protein and serum IgM level of 12,400 mg/dL. CT scans showed bulky adenopathy, and a BM biopsy demonstrated 80% LPL involvement. MYD88

Case 3. Patient with Refractory WM Disease.

A 46 year-old male was diagnosed with WM after presentation with fatigue and a hematocrit of 28.6%. BM biopsy showed 90% LPL involvement. CT scans were unremarkable, and serum IgM was 2,780 mg/dL. Treatment with bortezomib, dexamethasone and rituximab was started. After 3 cycles, no treatment response was observed. He then received 2 cycles of cyclophosphamide-based (CDR) therapy without response. Bendamustine was then initiated, and after two cycles serum IgM and hemoglobin levels remained unchanged. Everolimus was then begun and stopped due to non-response and worsening blood counts. A repeat BM biopsy confirmed unchanged WM disease.

</tr>
<tr>
<td>Hepatitis testing</td>
<td>Select patients with cryoglobulinemia, and who are being considered for rituximab.</td>
<td>Hepatitis C implicated in some cases of Type II cryoglobulinemia. Hepatitis B testing should be evaluated in all patients who are being considered for rituximab. HBsAg-positive WM patients may be also be candidates for prophylactic anti-viral therapy during rituximab therapy.</td>
</tr>
<tr>
<td>Iron, Total Iron Binding Capacity (TIBC)</td>
<td>Select patients with anemia.</td>
<td>Hepcidemia is common in WM and can impact iron absorption and re-utilization. If iron saturation (Iron/TIBC) is &lt;10-12% and not related to GI blood loss may be candidate for parenteral iron therapy.</td>
</tr>
<tr>
<td>Liver Function Tests (LFTs)</td>
<td>All patients.</td>
<td>Brain MRI with gadolinium should first be done to evaluate for parenchymal and meningeal involvement, and evaluate risk for hemiation. Cytological examination, white cell count with differential, flow cytometry, PCR for IgH rearrangements, as well as evaluation for MYD88L265P can be obtained to identify WM cells in CSF. If CSF positive, and Brain MRI is negative, MRI of entire spinal axis can be considered to evaluate for tumor presence if brain MRI is negative.</td>
</tr>
<tr>
<td>Lumbar puncture with CSF Examination.</td>
<td>Select patients with suspected Bing-Neel Syndrome.</td>
<td></td>
</tr>
<tr>
<td><strong>MYD88 Genotyping</strong></td>
<td><strong>Positron Em/ission Tomography (PET) Scan</strong></td>
<td><strong>Serum IgM, IgA, IgG levels (Quantitative)</strong></td>
</tr>
<tr>
<td>----------------------</td>
<td>---------------------------------------------</td>
<td>---------------------------------------------</td>
</tr>
<tr>
<td>MYD88 L265P positive &gt;90% of cases by AS-PCR, and can support WM diagnosis.(^4\text{-}^8) MYD88(^{WT}) is associated with inferior overall survival; and lower response rates and progression free survival to ibrutinib in WM patients.(^14\text{-}^{70}) Sanger sequencing for non-L265P MYD88 mutations can be considered in WM patients who by AS-PCR are negative for MYD88(^{L265P}) as other types of MYD88 mutations can occur in WM.(^70\text{-}^{106})</td>
<td>Select patients. No role for routine PET scans in WM unless disease transformation is suspected.(^31\text{-}^{34})</td>
<td>All patients. Obtain on warm bath for patients suspected of having cryoglobulinemia. Serum IgM levels can flare following rituximab, and should be carefully monitored in WM patients with high serum IgM levels (&gt;4,000 mg/dL).(^31\text{-}^{34}) Quantitative serum IgM levels can be used as surrogate marker for disease burden assessment.(^84) Serum IgA, IgG levels are subnormal in most WM patients and impacted by certain treatments.(^80) Patients with severely depressed IgG and recurring sinobronchial infections may benefit with intravenous immunoglobulin (IVIG) infusions.</td>
</tr>
<tr>
<td>Test Description</td>
<td>Patient Selection</td>
<td>Clinical Use</td>
</tr>
<tr>
<td>-------------------------------------------------------</td>
<td>-----------------------------------------------------------------------------------</td>
<td>------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>Serum Free Light Chains (SFLC)</td>
<td>Select patients with light-chain nephropathy, amyloidosis.</td>
<td>May be useful for serial assessment of treatment impact in patients with amyloidosis or light chain deposition disease.</td>
</tr>
<tr>
<td>Serum Myelin Associated Glycoprotein (MAG) titers</td>
<td>Select patients with peripheral sensory neuropathy, some forms of ataxia.</td>
<td>Positive in 25-50% of WM patients with disease related peripheral neuropathy. If negative, may consider further testing for anti-ganglioside M1 (GM1) and anti-sulfatide IgM antibodies.</td>
</tr>
<tr>
<td>Serum Protein Electrophoresis (SPEP)</td>
<td>All patients.</td>
<td>Demonstration of serum monoclonal IgM protein required for diagnosis of WM. Monoclonal IgM protein may be used as surrogate marker for assessing disease burden. Migration pattern of serum IgM and formation of higher order complexes on gels can complicate serial IgM protein assessment in some patients. Absence of serum IgM monoclonal protein by SPEP and immunofixation studies following therapy can be used to support attainment of a complete response (see Table 6).</td>
</tr>
<tr>
<td>Serum Viscosity</td>
<td>Select patients with suspected hyperviscosity symptoms and findings.</td>
<td>May be useful in assessing patients with hyperviscosity symptoms, though slow to be resulted and erratic readings commonly occur. Serum viscosity levels may be slow to be resulted, not reproducible or lack correlation to serum IgM levels. Serum IgM levels are more expedient and reliable for assessing patients with suspected hyperviscosity syndrome. Funduscopic examination should be done in all patients with hyperviscosity syndrome.</td>
</tr>
</tbody>
